The Editorial Board invites you to submit your letters to EPL

Six good reasons to publish with EPL

We want to work with you to help gain recognition for your high-quality work through worldwide visibility and high citations. As an EPL author, you will benefit from:

1. **Quality** – The 40+ Co-Editors, who are experts in their fields, oversee the entire peer-review process, from selection of the referees to making all final acceptance decisions.

2. **Impact Factor** – The 2009 Impact Factor increased by 31% to 2.893; your work will be in the right place to be cited by your peers.

3. **Speed of processing** – We aim to provide you with a quick and efficient service; the median time from acceptance to online publication is 30 days.

4. **High visibility** – All articles are free to read for 30 days from online publication date.

5. **International reach** – Over 2,000 institutions have access to EPL, enabling your work to be read by your peers in 100 countries.

6. **Open Access** – Experimental and theoretical high-energy particle physics articles are currently open access at no charge to the author. All other articles are offered open access for a one-off author payment (€1,000).

Details on preparing, submitting and tracking the progress of your manuscript from submission to acceptance are available on the EPL submission website [www.epletters.net](http://www.epletters.net).

If you would like further information about our author service or EPL in general, please visit [www.epljournal.org](http://www.epljournal.org) or e-mail us at info@epljournal.org.

Visit the EPL website to read the latest articles published in cutting-edge fields of research from across the whole of physics.

Each compilation is led by its own Co-Editor, who is a leading scientist in that field, and who is responsible for overseeing the review process, selecting referees and making publication decisions for every manuscript.

- Graphene
- Liquid Crystals
- High Transition Temperature Superconductors
- Quantum Information Processing & Communication
- Biological & Soft Matter Physics
- Atomic, Molecular & Optical Physics
- Bose–Einstein Condensates & Ultracold Gases
- Metamaterials, Nanostructures & Magnetic Materials
- Mathematical Methods
- Physics of Gases, Plasmas & Electric Fields
- High Energy Nuclear Physics

If you are working on research in any of these areas, the Co-Editors would be delighted to receive your submission. Articles should be submitted via the automated manuscript system at www.epletters.net

If you would like further information about our author service or EPL in general, please visit www.epljournal.org or e-mail us at info@epljournal.org

Abstract – We have developed a technique for precise measurement of small magnetic fields using nonlinear magneto-optic rotation (NMOR). The technique relies on the resonant laser beam being chopped. During the on time, the atoms are optically pumped into an aligned ground state ($\Delta m = 2$ coherence). During the off time, they freely precess around the magnetic field at the Larmor frequency. If the on-off modulation frequency matches (twice) the Larmor precession frequency, the rotation is resonantly enhanced in every cycle, thereby making the process like a repeated Ramsey measurement of the Larmor frequency. We study chopped-NMOR in a paraffin-coated Cs vapor cell. The out-of-phase demodulated rotation shows a Lorentzian peak of linewidth $85 \mu G$, corresponding to a sensitivity of $0.15 nG/\sqrt{Hz}$. We discuss the potential of this technique for the measurement of an atomic electric-dipole moment.

The well-known phenomenon of the rotation of the plane of polarization of near-resonant light passing through an atomic vapor in the presence of a longitudinal magnetic field, called magneto-optic rotation (MOR) or the Faraday effect, is understood to arise from the birefringence induced by the magnetic field. This phenomenon of MOR shows nonlinear effects when the light is sufficiently strong, as can be produced by a laser. In the simplest manifestation of nonlinear MOR (NMOR), the strong light field aligns the atom by inducing (through optical pumping) $\Delta m = 2$ coherences among the magnetic sublevels. The aligned atom undergoes Larmor precession about the longitudinal field, and causes additional rotation due to the precessed birefringence axis. The effect is nonlinear because the degree of optical alignment is dependent on the light intensity. NMOR in atomic vapor allows optical detection of zero-field level crossings in the shot noise limit, and has important applications in sensitive magnetometry [1,2], search for a permanent electric dipole moment (EDM) [3], and magnetic resonance imaging (MRI) [4].

In this work, we demonstrate a technique for measuring NMOR which is ideally suited for precision measurements.

(a)E-mail: vasant@physics.iisc.ernet.in

The basic idea is similar to a repeated Ramsey separated-oscillatory-fields [5] measurement of the Larmor precession frequency. This is achieved by chopping the laser beam on and off. During its on time, the atoms are optically pumped into an aligned $\Delta m = 2$ coherence of the ground state. During the off time, they freely precess around the magnetic field at the Larmor frequency. If the on-off modulation frequency matches the Larmor precession frequency, the atoms are realigned exactly when the light field comes back on, thus resonantly enhancing the optical pumping process. The process continues again for the next on-off cycle, so this is like a repeated Ramsey method. Demodulation of the rotation at the on-off modulation frequency shows a narrow peak at the value of the field where the modulation frequency is equal to $2 \times$ the Larmor frequency. The factor of 2 appears because the atomic alignment ($\Delta m = 2$ coherence) has two-fold symmetry.

As expected, the resonance width is limited by the decoherence time of the atomic alignment. Since the mean free path in a vapor cell at room temperature is several orders of magnitude larger than the cell size, the coherence can be destroyed by spin-exchange collisions with the walls. It has been shown that the use of paraffin coating on the walls reduces the ground-state depolarization rate and enhances the optical pumping signals [6]. We therefore use...
a paraffin-coated vapor cell for our experiments. We study the rotation on the $D_2$ line of Cs and observe linewidths of 85 $\mu$G. This width is smaller than the width of 136 $\mu$G seen for the zero-field resonance of normal NMOR, and shows that our technique gives a precise way of measuring the Larmor precession frequency.

A previous study of Ramsey fringes in NMOR had used a thermal beam of Rb atoms with separated pump and probe regions [7]. A strong pump was used to cause the alignment and a weak probe to measure the rotation, with a separation of 5 cm between the two regions. The resulting line shape was dispersive and had a width of about 6 mG. By contrast, we use the same beam for both pumping and probing. Still the rotation appears with high signal-to-noise ratio. The demodulated signal has the same dispersive lineshape as normal NMOR for the in-phase quadrature, but a near-perfect Lorentzian line shape for the out-of-phase quadrature. Furthermore, our linewidth is smaller than the zero-field resonance of normal NMOR, and shows that our technique gives a precise way of measuring the Larmor precession frequency.

Earlier work on NMOR has shown that modulation techniques, both frequency modulation (FM-NMOR [8]) and amplitude modulation (AMOR [9]), results in the kind of nonzero-field resonances that we observe. However, our simpler technique of chopping has several advantages. In contrast to FM-NMOR, we can operate at higher frequencies, we do not have phase delays, and we can lock the laser on resonance and average the resulting rotation. And, in comparison to AMOR, our technique gives Lorentzian peaks for the out-of-phase component while AMOR results in highly non-Lorentzian lineshapes [9]. Previous studies on AMOR have used both sine and square wave modulation but have always observed non-Lorentzian peaks. Recently, a combination of amplitude-modulated pump light and unmodulated probe light has been used to develop a self-oscillating magnetometer with high sensitivity, demonstrating the advantage of modulation techniques for commercial instruments based on NMOR [10].

The experimental schematic is shown in fig. 1. The NMOR measurements were done in a 80 mm diameter spherical cell with paraffin coating on the wall. The cell was kept inside a three-layer magnetic shield that reduced the ambient fields to below 0.1 mG. The cell had an axial solenoid coil of dimensions 140 mm diameter × 360 mm length which could produce fields up to 1 G, calibrated using a three-axis fluxgate magnetometer with 1 mG resolution. The field was measured to be uniform to better than 1% over the cell size. The field was swept linearly using a function generator.

The primary laser beam was derived from a home-built grating-stabilized diode laser with a linewidth of 1 MHz [11]. It was locked to the $F = 4 \rightarrow F' = 5$ closed transition of the $D_2$ line ($6S_{1/2} \rightarrow 6P_{3/2}$ transition) of $^{133}$Cs using saturated-absorption spectroscopy in a vapor cell. The laser beam in the experimental cell had a diameter of about 2 mm and power of 20 $\mu$W. The input was linearly polarized using a polarizing beamsplitter cube (PBS). It was passed through an acousto-optic modulator (AOM) to allow for fast switching. A second AOM was used to compensate for the frequency shift of the first one. After passing through the cell, the beam was split into its linear components using a Wollaston prism. The two intensities, $I_x$ and $I_y$, were made equal in the absence of a field (by adjusting the half-wave retardation plate in front of the cell). The rotation in the presence of a field is given by

$$\phi = \frac{1}{2} \arcsin \frac{I_x - I_y}{I_x + I_y} \approx \frac{I_x - I_y}{2(I_x + I_y)}, \quad (1)$$

where the approximation is valid for small rotation angles. Since the rotation in our experiments was on the order of a few mrad, the measured difference $I_x - I_y$ was taken to be the rotation signal.

We first consider the phenomenon of normal NMOR. The measured rotation as a function of applied magnetic field is shown in fig. 2. To understand the lineshape theoretically, consider the following. The origin of the NMOR effect is the creation of a ground-state alignment ($\Delta m = 2$ coherence), and the precession of this coherence in the magnetic field. The energy shift of a magnetic sublevel ($m_F$) in a magnetic field ($B$) is $g_F\mu_B m_F B$, where $g_F$ is the Landé $g$ factor and $\mu_B = 1.4$ MHz/G is the Bohr magneton. With the Larmor precession frequency defined as $\omega_L = g_F\mu_B B/\hbar$, the precession frequency of the alignment is simply $2\omega_L$. If the alignment is assumed to decohere exponentially at a rate $\Gamma_r/2$, then the time-averaged rotation angle can be derived as

$$\Phi = C \frac{2\omega_L}{(2\omega_L)^2 + \Gamma_r^2/4}, \quad (2)$$

where $C$ is a proportionality constant that depends on the degree of alignment. Thus, we see that the lineshape of normal NMOR is dispersive and centered at $\omega_L = 0$ (i.e., $B = 0$), exactly as observed in the figure. The solid curve
Chopped nonlinear magneto-optic rotation

is a fit to eq. (2) along with a linear term to account for the MOR effect. The fit yields a width of 136 \( \mu \text{G} \).

Let us now turn to the NMOR signals obtained with the chopped-NMOR technique, shown in fig. 3(a). To a rough approximation, one can say that the effect of the chopping is to modulate the atomic alignment at this frequency. Thus, if the chopping frequency is \( \omega_m \), the constant \( C \) in eq. (2) becomes \( C \cos(\omega_m t) \). The lock-in amplifier demodulates this signal at \( \omega_m \) to get the in-phase and out-of-phase quadratures. It is straightforward to see that the time-averaged rotation angle for the in-phase component is

\[
\Phi_{\text{ip}} = C \left[ \frac{D(\omega_L)}{2} + \frac{D(\omega_L - \omega_m)}{4} + \frac{D(\omega_L + \omega_m)}{4} \right],
\]

where

\[
D(x) = \frac{2x}{(2x)^2 + \Gamma_r^2/4}
\]

is the same dispersive function that appeared in eq. (2). That is, the in-phase rotation has two additional peaks compared to normal NMOR, which have the same lineshape but are centered at \( \pm \omega_m \) and have half the amplitude. This is exactly what is seen in the figure.

A similar analysis shows that the out-of-phase rotation is given by

\[
\Phi_{\text{op}} = C \left[ \frac{L(\omega_L - \omega_m)}{4} - \frac{L(\omega_L + \omega_m)}{4} \right],
\]

where

\[
L(x) = \frac{\Gamma_r}{(2x)^2 + \Gamma_r^2/4}
\]

is a Lorentzian function. As seen in the figure, the out-of-phase component is a sum of two Lorentzian peaks centered at \( \pm \omega_m \). The linewidth (i.e., full width at half-maximum) of each peak is \( \Gamma_r \), determined by the same decoherence rate as for normal NMOR. A fit to a Lorentzian lineshape yields a width of 85 \( \mu \text{G} \). This is smaller than the near-zero-field width of 136 \( \mu \text{G} \) seen for normal NMOR. It has been shown that the width of the NMOR resonance is critically dependent on both the residual field and gradients [12]. The relative importance of these imperfections is less when we consider the Larmor precession at the large field, as in the case of the chopped NMOR. This difference could account for the smaller linewidth that we observe.

An important application of our technique is to use it for the measurement of an EDM of an atom. In such applications, it is advantageous to use Rb as a co-magnetometer in the same cell. This is because Rb has a smaller EDM enhancement factor, defined as the ratio of the atomic EDM \( (d_A) \) to the intrinsic electron-EDM \( (d_e) \). The enhancement factor is 120.53 for Cs and 25.74 for Rb [13]. Therefore, both atoms will be sensitive to the magnetic field in the same way but to the electric field...
Cs differ by a factor of 2. below 10 magnetic-field inhomogeneities [12], we hope to reduce it for Rb are also about 20% smaller than that seen for Cs.

Fig. 4: (Color online) Use of Rb as a co-magnetometer. The NMOR signal demodulated at the chopping frequency \( f \) plotted as a function of the longitudinal magnetic field. Only the out-of-phase component is shown. The \( g \) factors of Rb and Cs differ by a factor of 2.

in a different way, which gives us an experimental handle on potential systematic errors. To enable this, we have filled our cell with both Rb and Cs. The experiment now has a second laser beam, which is locked to the \( F = 2 \rightarrow F' = 3 \) transition of the \( D_2 \) line in \( ^{87}\text{Rb} \) (at 780 nm). The two beams are linearly polarized in orthogonal directions and mixed on a PBS. Both beams are chopped at the same frequency and pass through a zero-order half-wave plate oriented at 45°, so that the rotation after the cell can be measured using the same Wollaston prism and photodiodes.

The out-of-phase component of the demodulated signal is shown in fig. 4. As expected, there are two sets of peaks, one for Cs and one for Rb. The peaks for Rb appear at a field that is exactly a factor of two smaller because its Landé \( g \) factor is \( 2 \times \) larger. The linewidths of the peaks for Rb are also about 20% smaller than that seen for Cs.

Since the width of the NMOR resonance depends on magnetic-field inhomogeneities [12], we hope to reduce it below 10 \( \mu \)G with better shielding and by using compensation coils. Indeed, widths of the zero-field NMOR resonance of order 2 \( \mu \)G have been observed using a four-layer shield [3]. However, even with our width of 85 \( \mu \)G, the shot-noise-limited sensitivity to a measurement of the magnetic field is \( \delta B = 0.15 \text{nG}/\sqrt{\text{Hz}} \). The measurement of an atomic EDM consists of measuring the shift in the Larmor precession frequency in the presence of an external electric field (\( E \)) due to the \( d_A \cdot \vec{E} \) interaction [14]. Thus, the sensitivity \( \delta d_A \) to an EDM is related to the smallest detectable change of the magnetic field as,

\[
\delta d_A = \frac{g_F \mu_B \delta B}{2E},
\]

where the factor of 2 accounts for the applied electric field being parallel or antiparallel to the magnetic field. This field reversal is built into our technique because we are sweeping the field from negative to positive values. Taking typical values of \( E = 10 \text{kV/cm} \) and an integration time of 10 days, the shot-noise limited sensitivity to an EDM measurement is \( \delta d_A = 1.2 \times 10^{-25} \text{cm} \), which is an order of magnitude better than the best measurement in Cs of \( d_{\text{Cs}} < -1.8 \times 10^{-24} \text{cm} \) [15]. This implies a 125\( \times \) smaller limit for \( d_A \) because of the enhancement factor in Cs.

In summary, we have developed a technique to measure a small magnetic field, or equivalently the Larmor precession frequency of an atom, using the nonlinear Faraday effect. The atoms are first aligned and then probed by chopping the laser at twice the Larmor frequency. Thus, it is like a Ramsey separated-oscillatory-fields method with the pump and probe regions separated in time. The rotation is modulated at the chopping frequency and shows a near-perfect Lorentzian line shape for the out-of-phase demodulated component. The observed linewidth of 85 \( \mu \)G (or frequency width of 60 Hz) holds much promise for the measurement of an atomic EDM. The best limit on the electron-EDM of \( 1.6 \times 10^{-27} \text{cm} \) comes from a measurement in Tl [16] because of its large enhancement factor of 585. In principle, the shot-noise limited sensitivity of our technique using Cs will allow us to reach the same precision even at the current linewidth. Further improvement in the linewidth seems possible with better shielding, but may be limited by Rb-Cs collisions because of the presence of Rb (for use as a co-magnetometer in an EDM experiment) in the same cell. We are right now in the process of evaluating this effect by improving the shielding, as also applying an \( E \) field for the EDM measurement.
